Experimental Modeling of Anxiety

Nimish L. Pathak, Sanjay B. Kasture, Nayna M. Bhatt and Ritesh G. Patel

ABSTRACT

Anxiety has much impact on human as well as animal behaviors. For evaluation of anxiolytic drug require both clinical and biological aspect of anxiety. We review the existing experimental models of anxiety like elevated plus maze apparatus, light dark model, open field apparatus, holeboard apparatus in order to promote further understanding of neurobiological aspects of anxiety.

Key words: Experimental modeling, anxiety, anxiety modeling.

INTRODUCTION

Anxiety is a psychological and physiological state characterized by cognitive, somatic, emotional, and behavioral components. These components combine to create an unpleasant feeling that is typically associated with uneasiness, apprehension, fear, or worry. It is a generalized mood condition that can often occur without an identifiable triggering stimulus (Wittchen et al., 1994; Korte SM et al., 2002).

Anxiety is classified in seven different groups: (1) Generalized anxiety disorder (GAD): It is a common chronic disorder characterized by long-lasting anxiety that is not focused on any one object or situation. So, person persistent fear and worry and become overly concerned with everyday matters (Arnold et al., 2006). (2) Panic disorder: It is a condition in which a person suffers from brief attacks of intense terror and apprehension, often marked by trembling, shaking, confusion, dizziness, nausea, difficulty breathing (Rollman et al., 2006). (3) Phobias: It is the single largest category of anxiety disorders which includes all cases in which fear and anxiety is triggered by a specific stimulus or situation (Markowitz et al., 1995). (4) Agoraphobia: It is specific anxiety about being in a place or situation where escape is difficult or embarrassing or where help may be unavailable (Schweizer et al., 1995). (5) Social anxiety disorder (SAD): It is described as an intense fear of negative public scrutiny or of public embarrassment or humiliation (Arborelius et al., 1999). (6) Obsessive–compulsive disorder (OCD): It is a type of anxiety disorder primarily characterized by repetitive obsessions (distressing, persistent, and intrusive thoughts or images) and compulsions (urges to perform specific acts or rituals (Nemeroff et al., 2004; Raison et al., 2003). (7) Post-traumatic stress disorder (PTSD): It is a result of an extreme situation, such as combat, natural disaster, rape, hostage situations, more serious kinds of child abuse, or even a serious accident. (8) Separation anxiety disorder: It is the feeling of excessive and inappropriate levels of anxiety over being separated from a person or place (Heim et al., 1999). Anxiety is extremely common, dramatic and debilitating disorders and it is now becoming clear that without knowledge of both clinical and biological aspects of anxiety, it is impossible to offer effective treatment strategies for the patients (Arborelius et al., 2004). We use animal models as experimental preparations developed in one species for the purposes of studying phenomena.
occurring in another species (Nemeroff et al., 2004; Raison et al., 2003; Belzung et al., 1999). Mice and humans share more than 90% of their genes, and animal models seem to be a useful tool in biomedical sciences, as evidenced by a notable increase in the number of active laboratories working in the field (Belzung et al., 1999; Belzung et al., 2001). Furthermore, animal models are particularly of help in situations when the impact of stress cannot be studied in humans because of ethical and other like reasons. However, the choice of which biological correlates to study is not easy, since problems with animal models of human psychiatric disorders include: (i) The difference between human’s and non-human’s nervous systems; (ii) The difficulty in determining analogous behaviors among species; and (iii) The need in extrapolation of results from animals to humans. Such problems most likely reflect a significant difference in etiology and complexity of anxious behaviors. In addition, it is important to know that the data derived from animal models are of value only to the extend that the models are valid, and that the level (severity) of the disorder evoked in animals may not be the level of human disorder we want to model (Willner et al., 1997).

**GENERAL CONCEPTS IN THE EXPERIMENTAL MODELING**

Behavioral models of animals have long been used to detect effects on, and impact of, anxiety (Arborelius et al., 1999; Paterson et al., 2001). A number of models (Tables I), based on animal emotional reactivity, have been designed and proven to be bi directionally sensitive to stressful manipulations, including those of anxiety (Espejo et al., 1997).

Since classification of experimental animal anxiety is as difficult as classification of human anxiety spectrum disorders (Nemeroff et al., 2004; Raison et al., 2003). The main task is therefore to differentiate between common and specific stress-related pathogenic mechanisms of the disorders belonging to this spectrum. As describe in Tables I Animal anxiety taxonomy can be based on the nature and type of stressors employed (Newport et al., 2002). Experimental models of anxiety can be acute, sub-chronic or chronic (Willner et al., 1997). Anxiety models can be based on: (i) Exploratory; (ii) Social; (iii) Defensive; (iv) Novelty-evoked; (v) Conditioned (active/passive avoidance); (vi) Anhedonic behavior; and (vii) conditioned fear-related behaviors (Wall et al., 2001). In addition, there are numerous models of anxiety based on prenatal and neonatal manipulations, including acute and chronic exposure to various stressors or different drugs (Espejo et al., 1997). Models of anxiety describe in table I can be "natural", based on measuring natural animal behaviors, or "artificial", utilizing behaviors not normally seen in natural conditions (Kalueff et al., 2003; King et al., 2002). Natural animal models aim to reproduce behavioral and pathological aspect of the disorder, to investigate the neurobiological mechanisms that are not easily amendable to study in humans, and allow a reliable evaluation of a number of external factors including pharmacological agents (Overall et al., 2002). Some importance animal models for anxiety are described below.

---

1. Elevated plus-maze apparatus (EPM)

Elevated plus-maze is the simplest apparatus to study anxiolytic response of almost all type of antianxiety agents. Exposure of the animals to novel maze alley evokes an approach-avoidance conflict which is stronger in open arm as compared to enclosed arm. Rodents (rats and mice) have aversion for high and open space and prefer enclosed arm and, therefore, spend greater amount of time in enclosed arm. When animals enter open arm, they freeze, become immobile, defecate and show fear-like movements. The plasma cortisol level is also reported to be increased, as a true reflection of anxiety (Kulkarni et al., 2009).

The elevated plus-maze was slightly modified from that used by Lister (Lister et al., 1987). Briefly, it consisted of two open arms (30 cm×30 cm×0.25 cm) and two enclosed arms (30 cm× 20 cm× 15 cm), extending from a central platform (5 cm× 5 cm) and raised 50 cm above floor level. The maze floor was constructed from black Plexiglas and the walls from clear Plexiglas. The conventional spatial-temporal measures recorded were the number of entries (all four paws on open or enclosed arms and expressed as percentage of total entries), the time spent on open arms (expressed as percentage of time spent on closed plus open arms), number of entries on enclosed arms and the time on the central platform. Ethologically derived measures were grooming, rearing, as an emotionally related parameter. A selective increase in the parameters of exploration of the open arms of the maze reveals an anxiolytic effect (Rodgers et al., 1992; Pellow et al., 1985).

2. Hole-board apparatus

The automatic hole-board apparatus consisted of a gray vinyl chloride box (50×50×50 cm) with four equidistant holes 3 cm in diameter in the floor. The area of the hole-board is divided with white ink into 24 smaller areas. An infrared beam sensor was installed on the wall to detect the numbers and duration of head-dipping behaviors. Other behavioral performance such as locus, distance and speed of movement of mice in the hole-board was recorded by the overhead color CCD camera. Data from CCD camera was collected through a custom-designed interface as a reflection signal. All of the data were analyzed and stored in a personal computer using analytical software, During 5 min we registered the number of head-dips, immobility, SAP (Streched attend Posture) rearing, grooming behavior, rears and also of displacements between the different areas (Takeda et al., 1998; File et al., 1975; Takeda et al., 1998).

3. Light dark apparatus

The light/dark test is based on the innate aversion of rodents to brightly illuminated areas and on the spontaneous exploratory behavior of the animals, applying mild stressors, i.e. novel environment and light (Griebel et al., 1993; Shimada et al., 1995). The apparatus consisted of two polyvinylchloride boxes (20 × 20 × 14 cm) covered with Plexiglas. One box was dark and covered with cardboard and the second box had a 100-watt bulb suspended 25 cm above it as the only source of light. An opaque tunnel (5 × 7 × 10 cm) between the two boxes. The apparatus was placed on a stand in the mouse room. The observer always set in the same position, next to the apparatus. Each mouse was placed individually in the darkened box and recordings were made over a 5-minute period, counting the time spent in the lit box (TLB) and the number of transitions (TRANS) across the tunnel, light box rear no, duration of light box rears, verticle activity urination deflection grooming. A mouse with all four paws in the destination box was said to have made a transition (Griebel et al., 1993; Shimada et al., 1995).

4. Open-field apparatus

The open field test (OFT) is a common measure of exploratory behavior both qualitatively and quantitatively. The most basic and common outcome of interest is “movement”; however, this can be influenced by motor output, exploratory drive, freezing or other fear-related behavior, sickness, relative time in circadian cycle, among many other variables (Asano et al., 1986; Crusio et al., 1989). Animals were removed from the home cage and placed directly into one corner of the open field (120cm×120cm). The floor was divided into a grid of 8×8 squares. Movement of the animal in the arena during the 10-minute testing session was recorded. After 10 minutes, the animal was removed and returned to the home cage, and the open-field arena was cleaned to prevent olfactory cues from affecting the behavior of subsequently tested rats. An observer blind to the experimental conditions coded the videotapes. Exploration was defined as the time spent in the inner 6×6 squares, whereas overall activity was defined as the number of squares crossed during the testing session. Although other parameter like distance in outer area grooming, latency stretch attend posture, latency of leave center area etc are measure (Shimada et al., 1995; Asano et al., 1986).

SOME METHODOLOGICAL ISSUES

The use of nearly all animal models has been extensively criticized in the literature for several reasons like First clinically important Symptoms of anxiety cannot be directly modeled in animals. Second, behavioral measures are often confounded and reflect changes in general activity, exploration and anxiety levels (Belzung et al., 2001; File et al., 2001; Rodgers et al., 1994). Third, there is poor correlation between different behavioral measures taken in the same test, or the same measures taken in several different tests (Flint et al., 2003). For example, grooming and defecation can often be seen as the only behaviors that change in the tests designed to measure anxiety behaviors (Chapillon et al., 1999). Even the simplest task distinguishing between horizontal exploration and locomotion in the open field, often mistakenly used synonymously in the literature – still requires further elaboration . Thus, since it is difficult to interpreta subjective anxiety based on a single behavioral measure, proper understanding of animal state is only possible through assessment of interaction between behavioral and physiological variables in the multivariate analysis (Belzung et al., 2001; Calatayud et al., 2001). Since various forms of psychopathologies in animals and humans can be characterized as context-regulation disorders,
subjects may sometimes produce "normal" behavior in inappropriate contexts. Thus, special analysis of behavioral contexts may be needed in the field of animal anxiety. Finally, it should be noted that animal emotional behavior is not just "plus" or "minus", but has several dimensions including anxiety, exploration, locomotion, risk assessment, general arousal and coping (Salome et al.; 2002). These dimensions interact with each other as well as with cognitive functions, giving a complex mosaic picture of behavior.

Therefore, the traditional quantitative behavioral methods (i.e., latency, frequency and duration parameters and their spatial, temporal or sequential patterns) to study animal stress are now combined with sophisticated analysis of "not just the presence or absence of these behaviors, but also whether or not acts, postures and gestures are fully developed in intensity, latency and patterning" (Barrett et al., 2000). Here appears a new cluster of issues. First, can we possibly model different subtypes of anxiety? For example, distinct subtypes of anxiety can be modeled in the same test, as suggested by Holmes and Rodgers (2001) for the elevated plus maze (single vs. repeated testing) (Holmes et al., 2001). Second, although anxiety is considered to be separate entities according to current diagnostic classifications, in clinical practice these two conditions often coexist. "Ideal" modeling of anxiety in animals presumes that in order to achieve better results we model either pathology separately. However, the important problem now is whether animals may possibly have comorbidity of anxiety. Theoretically, there are no reasons to rule out this possibility, and modeling comorbidity may represent certain interest for the researchers. Relatively few studies have been conducted, and there is a great need in developing specialized models which will allow assessing comorbidity in animals. For example, Wistar-Kyoto rats have been recently suggested as an animal model of anxiety based on their frequent anxiety-like freezing and depressive-like swim immobility (Tejani-Butt et al., 2003). Mice with targeted mutations of glucocorticoid receptors can also be the model of anxiety. Recently high-anxiety HAB rats have been suggested to be a reliable model of trait anxiety. Thus far, measuring comorbidity of anxiety or their comorbidity with other pathologies (e.g., addiction, alcoholism, etc.) may present an important direction for future studies (Salome et al., 2002).

VALIDITY AND RELIABILITY ASPECTS

The discussion focusing on different aspect of animal models validity is crucial for experimental modeling of anxiety. Validation is usually defined as the process by which the reliability and relevance of a method are established for specific purposes. Reliability is characterized by the reproducibility of a test within and between laboratories and over time. Since numerous differences exist between laboratories, good reproducibility at least within the same laboratory has to be established (Salome et al., 2002). As summarized in Table II, three principal and some additional validity criteria have been formulated and substantiated for animal models of anxiety and including predictive, construct, concurrent and convergent, discriminant, etiological and face validity (Geyer et al., 2001). In addition, genetical validation based on behavioral phenotyping approach, is becoming increasingly important. A "behavioral phenotype" refers to the specific and characteristic behavioral repertoire exhibited by animals with a specific genetic/chromosomal disorder. However, the question whether certain behaviors shall be apart of behavioral phenotype, is not clearly understood, especially since an association between behavior and syndrome, and between the syndrome and the gene, is not always clear cut and linear (Makarchuk et al., 2000). On validity basis, animal models can be classified as: (i) correlational – based on predictive validity; (ii) isomorphic – based on face validity; and (iii) homologous – based on construct validity. In general, a model shall fulfill all criteria in order to be a good model (Bai F et al., 2001).

CONCLUSIONS

As it was mentioned earlier, all animal models are generally seen as an attempt to reproduce a human disorder in a laboratory animal (McKinney et al., 1984). However, since the symptoms of psychiatric disorders are often being revised and their pathogenesis revisited (Takeda et al., 1998; Geyer et al., 2001; Borsini et al., 2002; Boyer et al., 2000), some caution is needed before claiming or using an animal model of anxiety. With this in mind, we shall always remember that, as McKinney (2001) incredibly timely and rightly noted, generating the perfect animal model does not represent a separate goal of research, rather the mode land its constant evolution represents an integral part of neuropsychobiology (McKinney et al., 1984). Moreover, modeling proceeds most effectively when psychiatrists, who are experts in the phenomena in question, join forces with neuroscientists, who know and understand available modeling tools (Davidson et al., 2002). Today, with the growing number of medical professionals being involved in basic research, and neuroscientists involved in clinically-oriented studies, an interdisciplinary view of neurobiology of anxiety and depression, linking human data to animal experimentation, is becoming extremely important.
